Two probable autochthonous introduced malaria cases in Italy in 2009-2011 and the risk of sporadic local transmission

We describe two cases of probable autochthonous introduced Plasmodium vivax malaria that occurred in two sites of South-Central Italy respectively in 2009 and 2011. Although the sources of infection were not detected, the conclusion of the epidemiological investigation was in favor of local transmission and therefore the cases were classified as autochthonous. Sporadic P. vivax cases transmitted by indigenous vectors may be considered possible in some areas of the country where vector abundance and environmental conditions are favorable to malaria transmission. We report on the possible risk of local vector-borne malaria transmission in territories of Italy where the vector abundance and environmental conditions are favorable.

KEY WORDS: Plasmodium vivax, autochthonous introduced malaria, Italy.

INTRODUCTION

Although soon after the World War II malaria was eliminated from Mediterranean countries, the rise in the average temperature of the earth (Gould and Higgs, 2009), environmental modifications, the increase of international travel, and socio-economic constraints recorded in the last decades (Vora, 2008), have raised the concern about the possible re-emergence of malaria in some of these countries, such as Italy, where malaria had been endemic before (Takken and Knols, 2007) and where competent vectors are still present. The recent outbreaks of malaria in Greece, although limited in size, are paradigmatic of this possible public health threat (Danis et al., 2011). In Italy, since the five-year eradication campaign in 1947-1951, one single confirmed case of autochthonous introduced P. vivax malaria has been recorded in Grosseto, Tuscany Region in 1997 (Baldari et al., 1998). Hereby, we report two probable but not proved autochthonous introduced malaria cases that occurred in Italy in the last three years.

CASE REPORTS

Case 1, 2009

A 41-year-old Caucasian man living in the outskirts of Rome was admitted to the intensive care unit of the local Hospital-following microscopic (blood smear observation, thick and thin films) and molecular (nested PCR analysis) (SNOUNOU and SINGH, 2002) diagnosis of P. vivax malaria. The patient had no history of previous malaria and reported a travel outside Italy in Santo Domingo, Dominican Republic, where he spent one-week holiday in 2003 and in 2004 in Sharm el Sheikh, Egypt, but he didn’t undertake any malaria prophylactic treatment on these occasions. He had no history of blood transfusions, tissue/organ transplantation, intravenous drug use, and no event of high fever in the previous six years. In July 2009, the month before the onset of symptoms, he had spent two weeks in two different holiday farms, one in Terracina, between 4 and 5 July, and the other in Pontinia, between 25 and 26 July. Both sites are located in the former ‘Pontine marshes’, a rural coastal plain of Central Italy, where malaria was hyperendemic until 1946. Although long term P. vivax relapses have been reported (Durante Mangoni et al., 2008) and could not be entirely ruled out in this case, the short stay in Santo Domingo, where foci of malaria still exist in limited areas, and the lack of a history of febrile attacks shortly after the travel made unlikely the hypothesis of a travel-acquired infection-orienting towards the hypothesis of an autochthonous case. After the detection of this case, the search for potential sources of infection was directed to the identification of migrants gametocyte carriers.
from endemic countries. A large number of regular migrants from India and Sri Lanka, employed in buffalo rearing and horticulture in green houses, live in a site which was very close to both holiday farms but no malaria case was identified among these people in 2009, through the regular surveillance system. Considering a minimum of 10–12 days for the malaria infection was probably acquired in the first half of July. Due to the late notification of the case to our reference centre at Istituto Superiore di Sanità, the entomological investigation started one month after malaria diagnosis. A single specimen of *Anopheles maculipennis* s.s. engorged female was found and collected in one of the animal shelters in the farms. Potential breeding sites suitable for anopheline larvae (few small canals for water supplying agriculture) were investigated but no adult mosquitoes or larvae were found. The entomological investigation conducted around the house of the patient in Rome also gave negative results (no adult of anopheline mosquitoes or suitable larval breeding sites were found).

**Case 2, 2011**

A 39-year-old Caucasian man resident in the mid town of Rende, a residential district close to the town of Cosenza, in Calabria Region, southern Italy, was hospitalized on 15 September 2011 with the same symptoms of Case 1 (high remittent fever, peaking every 48 hours and classical paroxysms with alternate cold, hot and sweating stages), although the onset of symptoms occurred on 1 September. Microscopic and molecular diagnosis of *P. vivax* malaria was performed as reported above. The patient did not report any blood transfusions, tissue/organ transplantation and intravenous drug use, and no remarkable febrile attacks during the previous six years. In his travel history he reported no recent travel in malaria-endemic areas, but a holiday in the Island of Santorini, Greece, in 2003 and a cruise along the coasts of the Mediterranean Sea in 2005. In August 2011, he spent the weekends in the village of Scalea, located along the Tyrrhenian coast, where there are some historically productive breeding sites where both *An. labranchiae* and *An. superpictus* occur (ROMI et al., 2001). Two investigations were carried out around the summer house in Scalea and in the area of the habitual residence in Rende to identify the source of infection but no gametocyte carriers were found. Three reception centers for African and Asian refugees, located in Cosenza Province, were not considered in our investigation because they were more than 10 km away from both houses of the index case and because the refugee people were under medical control (i.e. they were screened for infectious diseases upon arrival in Italy and had easy access to medical care when sick). The infection was probably acquired in mid-August, and the entomological investigation conducted on 27 and 28 September (a couple of weeks after malaria diagnosis) in the town of Scalea, revealed the presence of a possible anopheline breeding site in a canal that crosses the plain area of the town before flowing into the sea, close to the house of the patient. The canal was almost dry, with few residual pools of water along the edges, due to the presence of heavy vegetation. No anopheline larvae were found in those pools. Among the animal shelters inspected, only one resulted positive for anopheline mosquitoes: two engorged females of *An. labranchiae* were found in a cow shed of a farm located about 600 m from the summer residence of the patient. In Rende, only a single animal shelter was detected in the surrounding of the habitual residence: it was a small goat shelter located in a public garden about 200 m away from the case’s house, where 26 *Anopheles* mosquitoes belonging to the *An. maculipennis* complex were found, 21 of which were identified as *An. labranchiae* by ITS2 sequence analysis (Di Luca et al., 2004). One *An. maculipennis* s.s. IV instar larva was found in one of the two streams which were considered suitable breeding sites, located at 150 m and 600 m from the case’s house, respectively.

**DISCUSSION**

During the last 15 years (1997-2011), a total of 17 possible local cases of malaria occurred in Italy. Only one of them was likely transmitted by local vectors, thus fitting the criteria for an introduced case (WHO, 1963). The other 14 cases were classified as induced (nosocomial infection (n=7), post-transfusion (n=3), and post-transplant (n=1)) or imported (infected mosquitoes imported with baggage (n=3) (ROMI et al., 2010). The remaining two cases, discussed in this report, were classified as autochthonous introduced malaria. In Italy, as well as in other Mediterranean countries recently investigated for the risk of malaria re-introduction, the return to a situation of endemic malaria is unlikely, but the occurrence of sporadic, isolated cases of introduced *P. vivax* malaria may still be considered possible (Di Luca et al., 2000; ROMI et al., 2012). Even if the vulnerability of the Italian territory during the summer months seemed to be very low between 2000 and 2011 as shown in Fig. 1, recent entomological surveys carried out in areas historically considered ‘at risk’ for malaria showed a remarkable presence (or even high abundance in some places) of the main...
indigenous vector An. labranchiae, and confirmed its ability to bite humans both in the presence and in the absence of alternative hosts, indoors as well as outdoors [12-14]. A map displaying the current distribution of the potential malaria vectors and the regions of the country considered ‘at risk’, based on our own recent field collected data (2005-2011), is showed in Fig. 2. It should also be stressed that several direct or indirect effects of human activities in rural areas may quickly modify

the distribution and the abundance of the vectors, and may promote the contacts between mosquitoes and gametocyte carriers; these factors, together with the presence of a large non-immune human population, may have an impact on malaria reintroduction in newly vulnerable areas (BOCCOLINI et al., 2012).

In the light of the recent malaria outbreaks that occurred in Greece, the two cases reported here stress the importance of vigilance for this disease and the need to improve existing epidemiological and entomological surveillance systems for malaria. Finally, it should be mentioned that the occurrence of cases of autochthonous transmission of exotic vector borne infections in Europe may concern infections other than malaria. The recent outbreaks that occurred in some European countries such as Italy (West Nile and Chikungunya viruses) France, Croatia, and Portugal (Dengue virus) (REZZA et al., 2007; GOULD et al., 2010; LA RUCHE et al., 2010; GRANDADAM et al., 2010; GENERO-MARGAN et al., 2010; ECDC, 2012), and the widespread presence and abundance of the potential vectors of these diseases in our country, represent a clear threat to the public health which needs adequate counter measures.

ACKNOWLEDGMENTS

We thank Dr. C. Gnesivo (Department of Prevention, Local Health Unit Rome D), Dr. F. Perelli and Dr I. Valentini (Department of Prevention, Local Health Unit of Cosenza), Dr. F. Fabiano (Director of UOC Igiene Pubblica-Medicina Preventiva, Cosenza), Dr. F. Cesario (Department of Infectious Diseases, Hospital of Cosenza), Dr. P. Cavalcanti (Laboratory of Microbiology, Hospital of Cosenza), Dr. F. Pagnotta (Veterinary Services of the Local Health Unit of Cosenza) for their precious support in both logistic organization and epidemiological inquiries. A special thanks to D. Boccolini, A. Carinci, M. Di Luca, L. Gradoni, M. Menegon, G. Rezza, C. Severini, F. Severini, L. Toma, who collaborated to the epidemiological investigation.
